## ABSTRACT

Long short-term memory (LSTM) networks are a state-of-the-art technique for sequence learning. They are less commonly applied to financial time series predictions, yet inherently suitable for this domain. We deploy LSTM networks for predicting out-of-sample directional movements for the constituent stocks of the S&P 500 from 1992 until 2015. With daily returns of 0.46 percent and a Sharpe ratio of 5.8 prior to transaction costs, we find LSTM networks to outperform memory-free classification methods, i.e., a random forest (RAF), a deep neural net (DNN), and a logistic regression classifier (LOG). The outperformance relative to the general market is very clear from 1992 to 2009, but as of 2010, excess returns seem to have been arbitrated away with LSTM profitability fluctuating around zero after transaction costs. We further unveil sources of profitability, thereby shedding light into the black box of artificial neural networks. Specifically, we find one common pattern among the stocks selected for trading – they exhibit high volatility and a short-term reversal return profile. Leveraging these findings, we are able to formalize a rules-based short-term reversal strategy that yields 0.23 percent prior to transaction costs. Further regression analysis unveils low exposure of the LSTM returns to common sources of systematic risk – also compared to the three benchmark models.

## 1. Introduction

Prediction tasks on financial time series are notoriously difficult, primarily driven by the high degree of noise and the generally accepted, semi-strong form of market efficiency (Fama, 1970). Yet, there is a plethora of well-known capital market anomalies that are in stark contrast with the notion of market efficiency. For example, Jacobs (2015) or Green, Hand, and Zhang (2013) provide surveys comprising more than 100 of such capital market anomalies, which effectively rely on return predictive signals to outperform the market. However, the financial models used to establish a relationship between these return predictive signals, (the features) and future returns (the targets), are usually transparent in nature and not able to capture complex non-linear dependencies.

In the last years, initial evidence has been established that machine learning techniques are capable of identifying (non-linear) structures in financial market data, see Huck (2009, 2010),

Takeuchi and Lee (2013), Moritz and Zimmermann (2014), Dixon, Klabjan, and Bang (2015), and further references in Atsalakis and Valavanis (2009) as well as Sermpinis, Theofilatos, Karathanasopoulos, Georgopoulos, and Dunis (2013). Specifically, we expand on the recent work of Krauss, Do, and Huck (2017) on the same data sample for the sake of comparability. The authors use deep learning, random forests, gradient-boosted trees, and different ensembles as forecasting methods on all S&P 500 constituents from 1992 to 2015. One key finding is that deep neural networks with returns of 0.33 percent per day prior to transaction costs underperform gradient-boosted trees with 0.37 percent and random forests with 0.43 percent. The latter fact is surprising, given that deep learning has “dramatically improved the state-of-the-art in speech recognition, visual object recognition, object detection and many other domains” (LeCun, Bengio, and Hinton, 2015, p. 436). At first sight, we would expect similar improvements in the domain of time series predictions. However, Krauss et al. (2017, p. 695) point out that “neural networks are notoriously difficult to train” and that it “may well be that there are configurations in parameter space to further improve the performance” of deep learning.

In this paper, we primarily focus on deep learning, and on further exploring its potential in a large-scale time series prediction problem. In this respect, we make three contributions to the literature.

<sup>1</sup> The authors have benefited from many helpful discussions with Ingo Klein and three anonymous referees.

- First, we focus on long short-term memory (LSTM) networks, one of the most advanced deep learning architectures for sequence learning tasks, such as handwriting recognition, speech recognition, or time series prediction (Graves et al., 2009; Graves, Mohamed, & Hinton, 2013; Hochreiter & Schmidhuber, 1997; Schmidhuber, 2015). Surprisingly, to our knowledge, there has been no previous attempt to deploy LSTM networks on a large, liquid, and survivor bias free stock universe to assess its performance in large-scale financial market prediction tasks. Selected applications, as in Xiong, Nichols, and Shen (2015), focus on predicting the volatility of the S&P 500, on forecasting a small sample of foreign exchange rates (Giles, Lawrence, & Tsoi, 2001), or on assessing the impact of incorporating news for specific companies (Siah and Myers (2016)). We fill this void and apply LSTM networks to all S&P 500 constituents from 1992 until 2015. Hereby, we provide an in-depth guide on data preprocessing, as well as development, training, and deployment of LSTM networks for financial time series prediction tasks. Last but not least, we contrast our findings to selected benchmarks from the literature – a random forest (the best performing benchmark), a standard deep neural net (to show the value-add of the LSTM architecture), and a standard logistic regression (to establish a baseline). The LSTM network outperforms the memory-free methods with statistically and economically significant returns of 0.46 percent per day – compared to 0.43 percent for the RAF, 0.32 percent for the standard DNN, and 0.26 percent for the logistic regression. This relative advantage also holds true with regard to prediction accuracy where a Diebold–Mariano test confirms superior forecasts of the LSTM networks compared to the applied benchmarks. Our findings are largely robust to microstructural effects. Specifically, when we implement the LSTM strategy on volume-weighted-average-prices (VWAPs) instead of closing prices, we see a decline in profitability, but the results are still statistically and economically significant. The same holds true for a weekly implementation with lower turnover – even after introducing a one-day-waiting rule after the signal. Only as of 2010, the edge of the LSTM seems to have been arbitrated away, with LSTM profitability fluctuating around zero after transaction costs, and RAF profitability dipping strictly into the negative domain.
- Second, we aim at shedding light into the black box of artificial neural networks – thereby unveiling sources of profitability. Generally, we find that stocks selected for trading exhibit high volatility, below-mean momentum, extremal directional movements in the last days prior to trading, and a tendency for reversing these extremal movements in the near-term future.
- Third, we synthesize the findings of the latter part into a simplified, rules-based trading strategy that aims at capturing the

quintessence of the patterns the LSTM acts upon for selecting winning and losing stocks. A strategy that buys short-term extremal losers and sells short-term extremal winners leads to daily returns of 0.23 percent prior to transaction costs – so only about 50 percent of the LSTM returns. Regression analyses on systematic risk factors unveil a remaining alpha of 0.42 percent of the LSTM prior to transaction costs and generally lower exposure to common sources of systematic risk, compared to the benchmark models.

The remainder of this paper is organized as follows. Section 2 briefly covers the data sample, software packages, and hardware. Section 3 provides an in-depth discussion of our methodology, i.e., the generation of training and trading sets, the construction of input sequences, the model architecture and training as well as the forecasting and trading steps. Section 4 presents the results and discusses our most relevant findings in light of the existing literature. Finally, Section 5 concludes.

## 2. Data, software, hardware

### 2.1. Data

For the empirical application, we use the S&P 500 index constituents from Thomson Reuters. For eliminating survivor bias, we first obtain all month end constituent lists for the S&P 500 from Thomson Reuters from December 1989 to September 2015. We consolidate these lists into one binary matrix, indicating whether the stock is an index constituent in the subsequent month. As such, we are able to approximately reproduce the S&P 500 at any given point in time between December 1989 and September 2015. In a second step, for all stocks having ever been a constituent of the index during that time frame, we download daily total return indices from January 1990 until October 2015. Return indices are cum-dividend prices and account for all relevant corporate actions and stock splits, making them the most adequate metric for return computations. Following Clegg and Krauss (2018), we report average summary statistics in Table 1, split by industry sector. They are based on equal-weighted portfolios per sector, generated monthly, and constrained to index constituency of the S&P 500.

### 2.2. Software and hardware

Data preparation and handling is entirely conducted in Python 3.5 (Python Software Foundation, 2016), relying on the packages numpy (Van Der Walt, Colbert, & Varoquaux, 2011) and pandas (McKinney, 2010). Our deep learning LSTM networks are developed with keras (Chollet, 2016) on top of Google TensorFlow, a

**Table 1**

Average monthly summary statistics for S&P 500 constituents from January 1990 until October 2015, split by industry. They are based on equal-weighted portfolios per industry as defined by the Global Industry Classification Standards Code, formed on a monthly basis, and restricted to index constituency of the S&P 500. Monthly returns and standard deviations are denoted in percent.

powerful library for large-scale machine learning on heterogeneous systems (Abadi et al., 2015). Moreover, we make use of sci-kit learn (Pedregosa et al., 2011) for the random forest and logistic regression models and of H2O (H2O, 2016) for the standard deep net. For performance evaluation, we revert to R, a programming language for statistical computing (R Core Team, 2016) and the package PerformanceAnalytics by Peterson and Carl (2014). The LSTM network is trained on NVIDIA GPUs, all other models are trained on a CPU cluster.

### 3. Methodology

Our methodology consists of five steps. First, we split our raw data in study periods, composed of training sets (for in-sample training) and trading sets (for out-of-sample predictions). Second, we discuss the feature space and targets necessary for training and making predictions. Third, we provide an in-depth discussion of LSTM networks. Fourth, we briefly describe random forests, the deep net, and the logistic regression model we apply. Fifth, we develop the trading approach. The rest of this section follows the five step logic outlined above.

#### 3.1. Generation of training and trading sets

Following Krauss et al. (2017), we define a “study period” as a training-trading set, consisting of a training period of 750 days (approximately three years) and a trading period of 250 days (approximately one year). We split our entire data set from 1990 until 2015 in 23 of these study periods with non-overlapping trading periods. In other words, the study periods are rolling blocks of 1000 days. Training is done with rolling windows on the first 750 days, i.e., by rolling a look back input of 240 days (corresponding to the maximum feature length, see Section 3.2) across the block, and then predicting one day ahead. Trading is performed with the trained parameters on the last 250 days fully out-of-sample. Then, the entire system is rolled forward by 250 days – resulting in a total of 23 non-overlapping trading periods.

Let  $n_i$  denote the number of stocks that are a S&P 500 constituent at the very last day of the training period in study period  $i$ , so  $n_i$  is very close to 500.<sup>2</sup>

For the training set, we consider all  $n_i$  stocks with the history they have available. Some stocks exhibit a full 750 day training history, some only a subset of this time frame, for example, when they are listed at a later stage. The trading set is also composed of all  $n_i$  stocks. If a constituent exhibits no price data after a certain day within the trading period, it is considered for trading up until that day.<sup>3</sup>

#### 3.2. Feature and target generation

##### 3.2.1. Features – return sequences for LSTM networks

Let  $P^s = (p_t^s)_{t \in T}$  be defined as the price process of stock  $s$  at time  $t$ , with  $s \in \{1, \dots, n_i\}$  and  $R_t^{m,s}$  the simple return for a stock  $s$  over  $m$  periods, i.e.,

$$R_t^{m,s} = \frac{p_t^s}{p_{t-m}^s} - 1. \quad (1)$$

For the LSTM networks, we first calculate one-day ( $m = 1$ ) returns  $R_t^{1,s}$  for each day  $t$  and each stock  $s$ , and stack them in one large

feature vector  $V$  of dimension  $n_i \times T_{study}$ , where  $T_{study}$  denotes the number of days in the study period. Then, we standardize the returns by subtracting the mean ( $\mu_{train}^m$ ) and dividing them by the standard deviation ( $\sigma_{train}^m$ ) obtained from the training set:<sup>4</sup>

$$\tilde{R}_t^{m,s} = \frac{R_t^{m,s} - \mu_{train}^m}{\sigma_{train}^m}. \quad (2)$$

LSTM networks require sequences of input features for training, i.e., the values of the features at consecutive points in time. Our single feature is the standardized one-day return  $\tilde{R}_t^{1,s}$ . We opt for a sequence length of 240, thus comprising the information of approximately one trading year. Hence, we generate overlapping sequences of 240 consecutive, standardized one-day returns  $\tilde{R}_t^{1,s}$  in the following way: first, we sort the feature vector  $V$  by stock  $s$  and date  $t$  in ascending order. Then, we construct sequences of the form  $\{\tilde{R}_{t-239}^{1,s}, \tilde{R}_{t-238}^{1,s}, \dots, \tilde{R}_t^{1,s}\}$  for each stock  $s$  and each  $t \geq 240$  of the study period. For the first stock  $s_1$  the sequence hence consists of the standardized one-day returns  $\{\tilde{R}_1^{1,s_1}, \tilde{R}_2^{1,s_1}, \dots, \tilde{R}_{240}^{1,s_1}\}$ . The second sequence consists of  $\{\tilde{R}_2^{1,s_1}, \tilde{R}_3^{1,s_1}, \dots, \tilde{R}_{241}^{1,s_1}\}$  and so forth. An illustration is provided in Fig. 1. In total, each study period consists of approximately 380,000 of those sequences of which approximately 255,000 are used for in-sample training and approximately 125,000 are used for out-of-sample predictions.<sup>5</sup>

##### 3.2.2. Targets

For the sake of comparability, we follow Takeuchi and Lee (2013) and define a binary classification problem, i.e., the response variable  $Y_{t+1}^s$  for each stock  $s$  and date  $t$  can take on two different values. To define the two classes, we order all one-period returns  $R_{t+1}^{1,s}$  of all stocks  $s$  in period  $t + 1$  in ascending order and cut them into two equally sized classes. Class 0 is realized if the one-period return  $R_{t+1}^{1,s}$  of stock  $s$  is smaller than the cross-sectional median return of all stocks in period  $t + 1$ . Similarly, class 1 is realized if the one-period return of  $s$  is larger than or equal to the cross-sectional median.

#### 3.3. LSTM networks

The description of LSTM networks follows Graves (2013), Olah (2015), and Chollet (2016). Valuable additional introductions can be found in Karpathy (2015) and Britz (2015), providing step-by-step graphical walkthroughs and code snippets.

LSTM networks belong to the class of recurrent neural networks (RNNs), i.e., neural networks whose “underlying topology of inter-neuronal connections contains at least one cycle” (Medsker, 2000, p. 82). They have been introduced by Hochreiter and Schmidhuber (1997) and were further refined in the following years, e.g., by Gers, Schmidhuber, and Cummins (2000) and Graves and Schmidhuber (2005), to name a few. LSTM networks are specifically designed to learn long-term dependencies and are capable of overcoming the previously inherent problems of RNNs, i.e., vanishing and exploding gradients (Sak, Senior, & Beaufays, 2014).

LSTM networks are composed of an input layer, one or more hidden layers, and an output layer. The number of neurons in the input layer is equal to the number of explanatory variables (feature space). The number of neurons in the output layer reflects the output space, i.e., two neurons in our case indicating whether or not a stock outperforms the cross-sectional median in  $t + 1$ . The main characteristic of LSTM networks is contained in the hidden layer(s)

<sup>2</sup> The S&P 500 constituency count slightly fluctuates around 500 over time.

<sup>3</sup> The reason for exhibiting no more price data is generally due to delisting. Delisting may be caused by various reasons, such as bankruptcy, mergers and acquisitions, etc. Note that we do not eliminate stocks during the trading period in case they drop out of the S&P 500. The only criterion for being traded is that they have price information available for feature generation.

<sup>4</sup> It is key to obtain mean and standard deviation from the training set only, in order to avoid look-ahead biases.

<sup>5</sup> We have 1000 days in the study period and a sequence length of 240 days. As such, 760 sequences can be created per stock. Given that there are approximately 500 stocks in the S&P 500, we have a total of approximately 380,000 sequences.

Fig. 1. Construction of input sequences for LSTM networks (both, feature vector and sequences, are shown transposed).

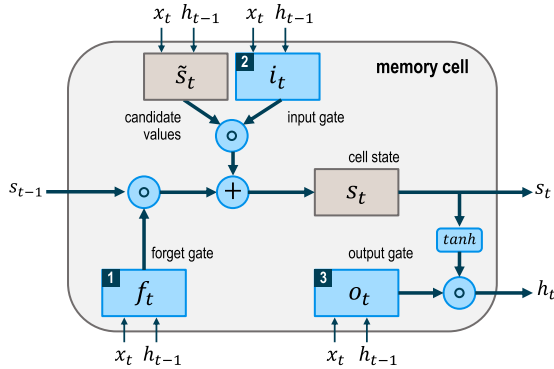

Fig. 2. Structure of LSTM memory cell following Graves (2013) and Olah (2015).

### 1 Forget gate:

Defines which information to remove from the memory (cell state)

### 2 Input gate:

Defines which information to add to the memory (cell state)

### 3 Output gate:

Defines which information from the memory (cell state) to use as output

consisting of so called memory cells. Each of the memory cells has three gates maintaining and adjusting its cell state  $s_t$ : a forget gate ( $f_t$ ), an input gate ( $i_t$ ), and an output gate ( $o_t$ ). The structure of a memory cell is illustrated in Fig. 2.

At every timestep  $t$ , each of the three gates is presented with the input  $x_t$  (one element of the input sequence) as well as the output  $h_{t-1}$  of the memory cells at the previous timestep  $t - 1$ . Hereby, the gates act as filters, each fulfilling a different purpose:

- The forget gate defines which information is removed from the cell state.
- The input gate specifies which information is added to the cell state.
- The output gate specifies which information from the cell state is used as output.

The equations below are vectorized and describe the update of the memory cells in the LSTM layer at every timestep  $t$ . Hereby, the following notation is used:

- $x_t$  is the input vector at timestep  $t$ .
- $W_{f,x}$ ,  $W_{f,h}$ ,  $W_{\tilde{s},x}$ ,  $W_{\tilde{s},h}$ ,  $W_{i,x}$ ,  $W_{i,h}$ ,  $W_{o,x}$ , and  $W_{o,h}$  are weight matrices.
- $b_f$ ,  $b_{\tilde{s}}$ ,  $b_i$ , and  $b_o$  are bias vectors.
- $f_t$ ,  $i_t$ , and  $o_t$  are vectors for the activation values of the respective gates.
- $s_t$  and  $\tilde{s}_t$  are vectors for the cell states and candidate values.
- $h_t$  is a vector for the output of the LSTM layer.

During a forward pass, the cell states  $s_t$  and outputs  $h_t$  of the LSTM layer at timestep  $t$  are calculated as follows:

In the first step, the LSTM layer determines which information should be removed from its previous cell states  $s_{t-1}$ . Therefore, the activation values  $f_t$  of the forget gates at timestep  $t$  are computed based on the current input  $x_t$ , the outputs  $h_{t-1}$  of the memory cells at the previous timestep ( $t - 1$ ), and the bias terms  $b_f$  of the forget gates. The sigmoid function finally scales all activation values

into the range between 0 (completely forget) and 1 (completely remember):

$$f_t = \text{sigmoid}(W_{f,x}x_t + W_{f,h}h_{t-1} + b_f). \quad (3)$$

In the second step, the LSTM layer determines which information should be added to the network's cell states ( $s_t$ ). This procedure comprises two operations: first, candidate values  $\tilde{s}_t$ , that could potentially be added to the cell states, are computed. Second, the activation values  $i_t$  of the input gates are calculated:

$$\tilde{s}_t = \tanh(W_{\tilde{s},x}x_t + W_{\tilde{s},h}h_{t-1} + b_{\tilde{s}}), \quad (4)$$

$$i_t = \text{sigmoid}(W_{i,x}x_t + W_{i,h}h_{t-1} + b_i). \quad (5)$$

In the third step, the new cell states  $s_t$  are calculated based on the results of the previous two steps with  $\odot$  denoting the Hadamard (elementwise) product:

$$s_t = f_t \odot s_{t-1} + i_t \odot \tilde{s}_t. \quad (6)$$

In the last step, the output  $h_t$  of the memory cells is derived as denoted in the following two equations:

$$o_t = \text{sigmoid}(W_{o,x}x_t + W_{o,h}h_{t-1} + b_o), \quad (7)$$

$$h_t = o_t \odot \tanh(s_t). \quad (8)$$

When processing an input sequence, its features are presented timestep by timestep to the LSTM network. Hereby, the input at each timestep  $t$  (in our case, one single standardized return) is processed by the network as denoted in the equations above. Once the last element of the sequence has been processed, the final output for the whole sequence is returned.

During training, and similar to traditional feed-forward networks, the weights and bias terms are adjusted in such a way that they minimize the loss of the specified objective function across

the training samples. Since we are dealing with a classification problem, we use cross-entropy as objective function.

The number of weights and bias terms being trained is calculated as follows: let  $h$  denote the number of hidden units of the LSTM layer, and  $i$  the number of input features, then the number of parameters of the LSTM layer that needs to be trained is:

$$4hi + 4h + 4h^2 = 4(hi + h + h^2) = 4(h(i + 1) + h^2). \quad (9)$$

Hereby  $4hi$  refers to the dimensions of the four weight matrices applied to the inputs at each gate, i.e.,  $W_{f,x}$ ,  $W_{\bar{s},x}$ ,  $W_{i,x}$ , and  $W_{o,x}$ . The  $4h$  refers to the dimensions of the four bias vectors ( $b_f$ ,  $b_{\bar{s}}$ ,  $b_i$ , and  $b_o$ ). Finally, the  $4h^2$  corresponds to the dimensions of the weight matrices applied to the outputs at the previous timestep, i.e.,  $W_{f,h}$ ,  $W_{\bar{s},h}$ ,  $W_{i,h}$ , and  $W_{o,h}$ .

For the training of the LSTM network, we apply three advanced methods via keras. First, we make use of RMSprop, a mini-batch version of rprop (Tieleman & Hinton, 2012), as optimizer. The selection of RMSprop is motivated from the literature as it is “usually a good choice for recurrent neural networks” (Chollet, 2016). Second, following Gal and Ghahramani (2016), we apply dropout regularization within the recurrent layer. Hereby, a fraction of the input units is randomly dropped at each update during training time, both at the input gates and the recurrent connections, resulting in reduced risk of overfitting and better generalization. Based on initial experiments on the year 1991 (which is not used as part of the out-of-sample trading periods), we have observed that higher dropout values go along with a decline in performance and therefore settled on a relatively low dropout value of 0.1. Third, we make use of early stopping to dynamically derive the number of epochs for training for each study period individually and to further reduce the risk of overfitting. Hereby, the training samples are split into two sets: one training and one validation set. The first set is used to train the network and to iteratively adjust its parameters so that the loss function is minimized. After each epoch (one pass across the samples of the first set), the network predicts the unseen samples from the validation set and a validation loss is computed. Once the validation loss does not decrease for *patience* periods, the training is stopped and the weights of the model with the lowest validation loss is restored (see ModelCheckpoint callback in Chollet, 2016). Following Granger (1993), who suggests to hold back about 20 percent of the sample as “post-sample” data, we use 80 percent of the training samples as training set and 20 percent as validation set (samples are assigned randomly to either training or validation set), a maximum training duration of 1000 epochs, and an early stopping patience of 10. The specified topology of our trained LSTM network is hence as follows:

- Input layer with 1 feature and 240 timesteps.
- LSTM layer with  $h = 25$  hidden neurons and a dropout value of 0.1. This configuration yields 2752 parameters for the LSTM, leading to a sensible number of approximately 93 training examples per parameter. This value has been chosen in analogy to the configuration of the deep net in Krauss et al. (2017). A high number of observations per parameter allows for more robust estimates in case of such noisy training data, and reduces the risk of overfitting.
- Output layer (dense layer) with two neurons and softmax activation function<sup>6</sup> – a standard configuration.

### 3.4. Benchmark models – random forest, deep net, and logistic regression

For benchmarking the LSTM, we choose random forests, i.e., a robust yet high-performing machine learning method, a stan-

dard deep net, i.e., for showing the advantage of the LSTM, and a logistic regression, i.e., a standard classifier as baseline. Note that random forests, standard deep nets, and the feature generation for memory-free methods follow the specifications outlined in Krauss et al. (2017) for benchmarking reasons. Specifically, we use cumulative returns  $R_t^{m,s}$  as features with  $m \in \{1, \dots, 20\} \cup \{40, 60, \dots, 240\}$ , see Eq. (1) and the same targets as defined in Section 3.2.2. For the logistic regression model, we standardize the returns as denoted in Eq. (2).<sup>7</sup> In the subsequent paragraphs, we briefly outline how we calibrate the benchmarking methods.

**Random forest:** The first algorithm for random decision forests has been suggested by Ho (1995), and was later expanded by Breiman (2001). Simply speaking, random forests are composed of many deep yet decorrelated decision trees built on different bootstrap samples of the training data. Two key techniques are used in the random forest algorithm – random feature selection to decorrelate the trees and bagging, to build them on different bootstrap samples. The algorithm is fairly simple: for each of the  $B$  trees in the committee, a bootstrap sample is drawn from the training data. A decision tree is developed on the bootstrap sample. At each split, only a subset  $m$  of the  $p$  features is available as potential split criterion. The growing stops once the maximum depth  $J$  is reached. The final output is a committee of  $B$  trees and classification is performed as majority vote. We set the number of trees  $B$  to 1000, and maximum depth to  $J = 20$ , allowing for substantial higher order interactions. Random feature selection is left at a default value of  $m = \sqrt{p}$  for classification, see Pedregosa et al. (2011).

We use a random forest as benchmark for two compelling reasons. First, it is a state-of-the-art machine learning model that requires virtually no tuning and usually delivers good results. Second, random forests in this configuration are the best single technique in Krauss et al. (2017) and the method of choice in Moritz and Zimmermann (2014) – a large-scale machine learning application on monthly stock market data. As such, random forests serve as a powerful benchmark for any innovative machine learning model.

**Deep neural network:** We deploy a standard DNN to show the relative advantage of LSTM networks. Specifically, we use a feed forward neural network with 31 input neurons, 31 neurons in the first, 10 in the second, 5 in the third hidden layer, and 2 neurons in the output layer. The activation function is maxout with two channels, following Goodfellow, Warde-Farley, Mirza, Courville, and Bengio (2013), and softmax in the output layer. Dropout is set to 0.5, and L1 regularization with shrinkage 0.00001 is used – see Krauss et al. (2017) for further details.

**Logistic regression:** As baseline model, we also deploy logistic regression. Details about our implementation are available in the documentation of sci-kit learn (Pedregosa et al., 2011) and the references therein. The optimal L2 regularization is determined among 100 choices on a logarithmic scale between 0.0001 and 10,000 via 5-fold cross-validation on the respective training set and L-BFGS is deployed to find an optimum, while restricting the maximum number of iterations to 100. Logistic regression serves as a baseline, so that we can derive the incremental value-add of the much more complex and computationally intensive LSTM network in comparison to a standard classifier.

### 3.5. Forecasting, ranking, and trading

For all models, we forecast the probability  $\hat{P}_{t+1|t}^s$  for each stock  $s$  to out-/underperform the cross-sectional median in period  $t + 1$ , making only use of information up until time  $t$ . Then, we rank all stocks for each period  $t + 1$  in descending order of this probability.

<sup>6</sup> Alternatively, one output neuron with a sigmoid activation function would also be a valid setup.

<sup>7</sup> We perform no standardization of the returns for the other two models as this is automatically carried out for the deep neural network in its H2O implementation, or not required in case of the random forest.

**Table 2**

Panel A:  $p$ -values of Diebold–Mariano (DM) test for the null hypothesis that the forecasts of method  $i$  have inferior accuracy than the forecasts of method  $j$ . Panel B:  $p$ -values of the Pesaran–Timmermann (PT) test for the null hypothesis that predictions and responses are independently distributed. Both panels are based on the  $k = 10$  portfolio from December 1992 to October 2015.

A: DM test					B: PT test		
$i$	$j =$	LSTM	RAF	DNN	LOG	Method	Result
LSTM	–	–	0.0143	0.0037	0.0000	LSTM	0.0000
RAF	–	0.9857	–	0.3180	0.0000	RAF	0.0000
DNN	–	0.9963	0.6820	–	0.0000	DNN	0.0000
LOG	–	1.0000	1.0000	1.0000	–	LOG	0.0000

The top of the ranking corresponds to the most undervalued stocks that are expected to outperform the cross-sectional median in  $t + 1$ . As such, we go long the top  $k$  and short the flop  $k$  stocks of each ranking, for a long-short portfolio consisting of  $2k$  stocks – see [Huck \(2009, 2010\)](#).

## 4. Results

Our results are presented in three stages. First, we analyze returns prior to and after transaction costs of 5 bps per half-turn, following [Avellaneda and Lee \(2010\)](#), and contrast the performance of the LSTM network against the random forest, the deep neural net, and the logistic regression. Second, we derive common patterns within the top and flop stocks, thus unveiling sources of profitability. Third, we develop a simplified trading strategy based on these findings, and show that we can achieve part of the LSTM performance by capturing the most visible pattern with a transparent trading rule.

### 4.1. Performance review

#### 4.1.1. Overview

First, we analyze the characteristics of portfolios consisting of  $2k$  stocks, i.e., the top  $k$  stocks we go long, and the flop  $k$  stocks we go short. We choose  $k \in \{10, 50, 100, 150, 200\}$  and compare the performance of the novel LSTM with the other approaches along the dimensions mean return per day, annualized standard deviation, annualized Sharpe ratio, and accuracy – prior to transaction costs.

We see the following trends. Irrespective of the portfolio size  $k$ , the LSTM shows favorable characteristics vis-a-vis the other approaches. Specifically, daily returns prior to transaction costs are at 0.46 percent, compared to 0.43 percent for the RAF, 0.32 percent for the DNN, and 0.26 for the LOG for  $k = 10$ . Also for larger portfolio sizes, the LSTM achieves the highest mean returns per day, with the exception of  $k = 200$ , where it is tied with the RAF. With respect to standard deviation – a risk metric – the LSTM is on a similar level as the RAF, with slightly lower values for  $k = 10$ , and slightly higher values for increasing portfolio sizes. Both LSTM and RAF exhibit much lower standard deviation than the DNN and the logistic regression – across all levels of  $k$ . Sharpe ratio, or return per unit of risk, is highest for the LSTM up until  $k = 100$ , and slightly less than the RAF for even larger portfolios, when the lower standard deviation of the RAF outweighs the higher return of the LSTM. Accuracy, meaning the share of correct classifications, is an important machine learning metric. We see a clear advantage of the LSTM for the  $k = 10$  portfolio, a slight edge until  $k = 100$ , and a tie with the RAF for increasing sizes.

We focus our subsequent analyses on the long-short portfolio with  $k = 10$ .

#### 4.1.2. Details on predictive accuracy

The key task of the employed machine learning methods is to accurately predict whether a stock outperforms its cross-sectional

median or not. In this paragraph, we benchmark the predictive accuracy of the LSTM forecasts against those of the other methods, and against random guessing. Furthermore, we compare the financial performance of the LSTM with 100,000 randomly generated long-short portfolios.

First, we deploy the [Diebold and Mariano \(1995\)](#) (DM) test to evaluate the null that the forecasts of method  $i$  have inferior accuracy than the forecasts of method  $j$ , with  $i, j \in \{LSTM, RAF, DNN, LOG\}$  and  $i \neq j$ . For each forecast of each method, we assign a 0 in case the individual stock of the  $k = 10$  portfolio is correctly classified and a 1 otherwise, and use this vector of classification errors as input for the DM test. In total, we hence consider  $5750 \times 2 \times k = 115,000$  individual forecasts for the stocks in the  $k = 10$  portfolio for 5750 trading days in total. Results are depicted in panel A of [Table 2](#). In line one, for the null that the LSTM forecast is inferior to the forecasts of RAF, DNN, or LOG, we obtain  $p$ -values of 0.0143, 0.0037, and 0.0000, respectively. If we test at a five percent significance level, and apply a Bonferroni correction for three comparisons, the adjusted significance level is 1.67 percent, and we can still reject the individual null hypotheses that the LSTM forecasts are less accurate than the RAF, DNN, or LOG forecasts. Hence, it makes sense to assume that the LSTM forecasts are superior to those of the other considered methods. Similarly, we can reject the null that the RAF forecasts are inferior to the LOG forecasts as well as the null that the DNN forecasts are inferior to the LOG forecasts. In other words, the predictions of the sophisticated machine learning approaches all outperform those of a standard logistic regression classifier. Apparently, the former are able to capture complex dependencies in our financial time series data that cannot be extracted by a standard logistic regression. However, from the DM test matrix, we cannot infer that the RAF forecasts outperform the DNN forecasts or vice versa – both methods seem to exhibit similar predictive accuracy. Our key finding is though, that the LSTM network – despite its significantly higher computational cost – is the method of choice in terms of forecasting accuracy.

Second, we use the Pesaran–Timmermann (PT) test to evaluate the null hypotheses that prediction and response are independently distributed for each of the forecasting methods. We find  $p$ -values of zero up to the fourth digit, suggesting that the null can be rejected at any sensible level of significance. In other words, each machine learning method we employ exhibits statistically significant predictive accuracy.

Third, we provide a statistical estimate for the probability of the LSTM network having randomly achieved these results. For  $k = 10$ , we consider a total of  $5750 \times 10 \times 2 = 115,000$  top and flop stocks, of which 54.3 percent are correctly classified. If the true accuracy of the LSTM network was indeed 50 percent, we could model the number of “successes”, i.e., the number of correctly classified stocks  $X$  in the top/flop with a binomial distribution, so  $X \sim B(n = 115,000, p = 0.5, q = 0.5)$ . For such a large  $n$ ,  $X \stackrel{appr.}{\sim} \mathcal{N}(\mu = np, \sigma = \sqrt{npq})$ . Now, we can easily compute the probability of achieving more than 54.3 percent accuracy, if the LSTM network had a true accuracy of 50 percent. We use the R package Rmpfr of [Maechler \(2016\)](#) to evaluate multiple-precision

Fig. 3. Daily performance characteristics for long-short portfolios of different sizes: mean return (excluding transaction costs), standard deviation, annualized Sharpe ratio (excluding transaction costs), and accuracy from December 1992 to October 2015.

Fig. 4. Empirical distribution of mean daily returns of 100,000 sampled monkey trading long-short portfolios (excluding transaction costs).

floating point numbers and compute a probability of  $2.7742e-187$  that a random classifier performs as well as the LSTM by chance alone.

Finally, we assess the financial performance of 100,000 randomly sampled portfolios in the sense of Malkiel's monkey throwing darts at the Wall Street Journal's stock page (Malkiel, 2007). Hereby, we randomly sample 10 stocks for the long and 10 stocks for the short portfolio without replacement for each of the 5750 trading days. All these portfolios over the 5750 days can be interpreted as those being picked by one monkey. Then, we compute the mean average daily return of the combined long-short portfolios over these 5750 days to evaluate the monkey's performance. The results of 100,000 replications, i.e., of 100,000 different monkeys, are illustrated in Fig. 4. As expected, we see an average daily return of zero prior to transaction costs. More importantly, even the best performing "monkey" with an average daily return of 0.05 percent, does not even come close to the results of the applied models shown in Fig. 3.

#### 4.1.3. Details on financial performance

Table 3 provides insights of the financial performance of the LSTM, compared to the benchmarks, prior to and after transaction costs.

**Return characteristics:** In panel A of Table 3, we see that the LSTM exhibits favorable return characteristics. Mean returns of 0.46 percent before and 0.26 percent after transaction costs are statistically significant, with a Newey–West  $t$ -statistic of 16.9336 before and 9.5792 after transaction costs, compared to a critical value of 1.9600 (5 percent significance level). The median is only slightly smaller than the mean return, and quartiles as well as minimum and maximum values suggest that results are not caused by outliers. The share of positive returns is at 55.74 percent after transaction costs, an astonishingly high value for a long-short portfolio. The second best model is the RAF, with mean returns of 0.23 percent after transaction costs, albeit at slightly higher standard deviation (0.0209 LSTM vs. 0.0215 RAF). The DNN places third with mean returns of 0.12 percent per day after transaction costs – still statistically significant – compared to the logistic regression. The simplest model achieves mean returns of 0.06 percent per day after transaction costs, which are no longer significantly different from zero (Newey–West  $t$ -statistic of 1.6666 compared to critical value of 1.9600). Note that the LSTM shows strong performance compared to the literature. The ensemble in Krauss et al. (2017), which consists of a deep net, gradient-boosted trees, and a random forest yields average returns of 0.25 percent per day on the same time frame, data set, and after transaction costs. In other words,

**Table 3**

Panels A, B, and C illustrate performance characteristics of the  $k = 10$  portfolio, before and after transaction costs for LSTM, compared to RAF, DNN, LOG, and to the general market (MKT) from December 1992 to October 2015. MKT represents the general market as in Kenneth R. French's data library, see [here](#). Panel A depicts daily return characteristics. Panel B depicts daily risk characteristics. Panel C depicts annualized risk-return metrics. Newey–West standard errors with a one-lag correction are used.

		Before transaction costs				After transaction costs

the LSTM as single model achieves a slightly stronger performance than a fully-fledged ensemble.

**Risk characteristics:** In panel B of Table 3, we observe a mixed picture with respect to risk characteristics. In terms of daily value at risk (VaR), the LSTM achieves second place after the RAF, with a 1-percent VaR of –5.45 percent compared to –4.95 percent for the RAF. The riskiest strategy stems from the logistic regression model, where a loss of –7.66 percent is exceeded in one percent of all cases – more than twice as risky as a buy-and-hold investment in the general market. However, the LSTM has the lowest maximum drawdown of 52.33 percent – compared to all other models and the general market.

**Annualized risk-return metrics:** In panel C of Table 3, we analyze risk-return metrics on an annualized basis. We see that the LSTM achieves the highest annualized returns of 82.29 percent after transaction costs, compared to the RAF (67.87 percent), the DNN (24.60 percent), the LOG (7.11 percent) and the general market (9.25 percent). Annualized standard deviation is at the second lowest level of 33.23 percent, compared to all benchmarks. The Sharpe ratio scales excess return by standard deviation, and thus can be interpreted as a signal-to-noise ratio in finance, or the return per unit of risk. We see that the LSTM achieves the highest level of 2.34, with the RAF coming in second with 1.87, while all other methods have a Sharpe ratio well below 1.0.

From a financial perspective, we have two key findings. First, the LSTM outperforms the RAF by a clear margin in terms of return characteristics and risk-return metrics. We are thus able to show that choosing LSTM networks – which are inherently suitable for time series prediction tasks – outperform shallow tree-based models as well as standard deep learning. Second, we demonstrate that a standard logistic regression is not able to capture the same level of information from the feature space – even though we perform in-sample cross-validation to find optimal regularization values.

#### 4.1.4. A critical review of LSTM profitability over time

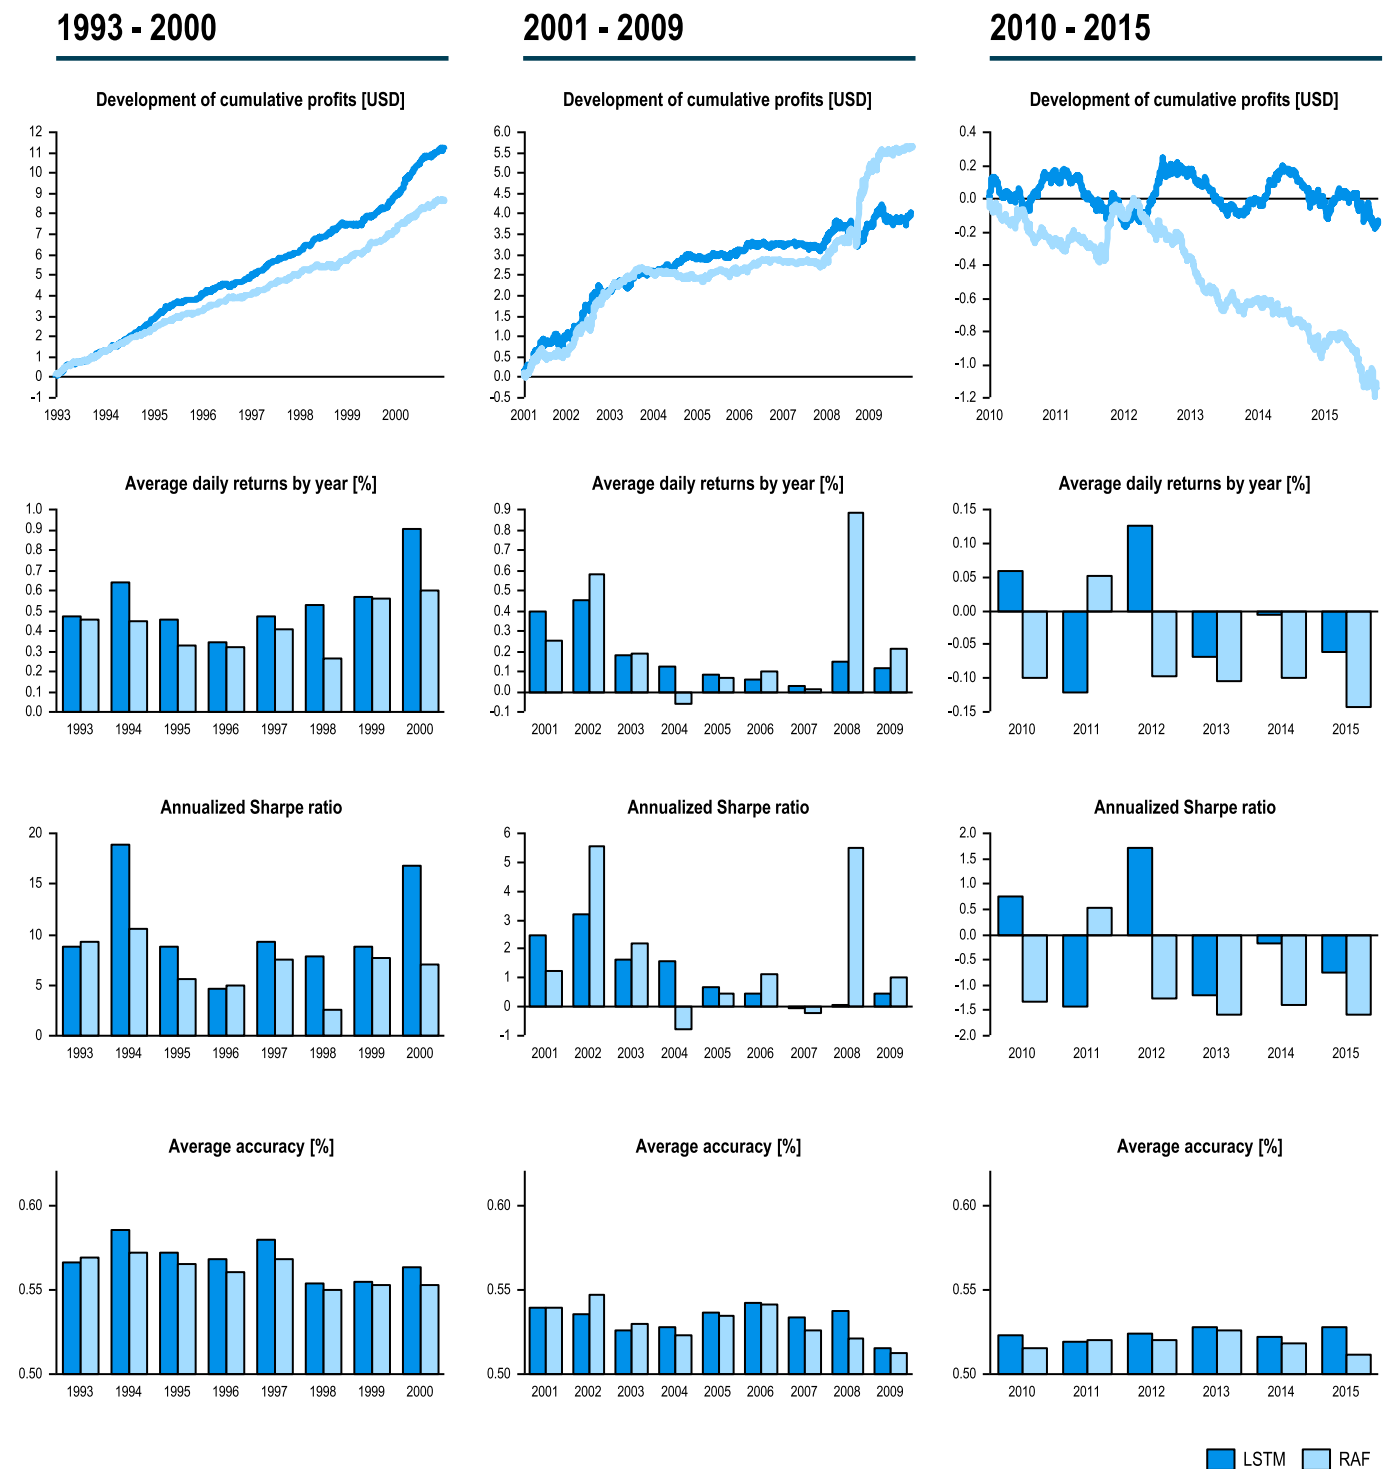

In Fig. 5, we display strategy performance over time, i.e., from January 1993 to October 2015. We focus on the most competitive techniques, i.e., the LSTM and the random forest.

**1993/01–2000/12:** These early times are characterized by strong performance – with the LSTM being superior to the RAF with respect to average returns per day, Sharpe ratio, and accuracy in almost all years. Cumulative payouts on 1 USD average invest per day reach a level of over 11 USD for the LSTM and over 8 USD for the RAF until 2000. When considering this outperformance, it is important to note that LSTM networks have been introduced in 1997, and can only be feasibly deployed ever since the emergence of GPU computing in the late 2000s. As such, the exceptionally high returns in the 90s may well be driven by the fact that LSTMs were either unknown to or completely unfeasible for the majority of market professionals at that time. A similar argument holds true for random forests.

**2001/01–2009/12:** The second period corresponds to a time of moderation. The LSTM is still able to produce positive returns after transaction costs in all years, albeit at much lower levels compared to the 90s. When considering cumulative payouts, we see that the outperformance of the LSTM compared to the random forest persists up to the financial crisis. A key advantage of these tree-based methods is their robustness to noise and outliers – which plays out during such volatile times. The RAF achieves exceptionally high returns and consistent accuracy values at a Sharpe ratio of up to 6. As such, total payouts on 1 USD investment amount to 4 USD for the LSTM, and to 5.6 USD for the RAF – with the majority of the RAF payouts being achieved during the financial crisis.

It seems reasonable to believe that this period of moderation is caused by an increasing diffusion of such strategies among industry professionals, thus gradually eroding profitability. However, for the RAF, the global financial crisis in 2008/2009 constitutes an exception – with a strong resurgence in profitability. Following the

**Fig. 5.** Contrast of LSTM and RAF performance from January 1993 to October 2015 for the  $k = 10$  portfolio, i.e., development of cumulative profits on 1 USD average investment per day, average daily returns by year, annualized Sharpe ratio, and average accuracy per year, after transaction costs.

literature, these profits may be driven by two factors. First, it is reasonable to believe that investors are “losing sight of the trees for the forest” (Jacobs and Weber, 2015, p. 75) at times of financial turmoil – thus creating realtive-value arbitrage opportunities, see Clegg and Krauss (2018). Second, at times of high volatility, limits to arbitrage are exceptionally high as well, making it hard to capture such relative-value arbitrage opportunities. Specifically, short selling costs may rise for hard to borrow stocks – see Gregoriou (2012), Engelberg, Reed, and Ringgenberg (2017), or, in even more

severe cases, short-selling may be banned altogether. But also the long side is affected, e.g., when widening spreads and decreasing liquidity set a cap on returns.

**2010/01–2015/10:** The third period corresponds to a time of deterioration. The random forest loses its edge, and destroys more than 1 USD in value, based on an average investment of 1 USD per day. By contrast, the LSTM continues realizing higher accuracy scores in almost all years and is able to keep capital approximately constant, after transaction costs. When comparing to the literature,

**Fig. 6.** Time-varying share of industries in the  $k = 10$  portfolio minus share of these industries in the S&P 500, calculated over number of stocks. A positive value indicates that the industry is overweighted and vice versa.

it is remarkable to see that the ensemble presented in [Krauss et al. \(2017\)](#) also runs into a massive drawdown as of 2010 – whereas the single-model LSTM returns fluctuate around zero. Regardless, the edge of the presented machine learning methods seems to have been arbitrated away. This effect can be observed in many academic research papers targeting quantitative strategies – see, for example, [Bogomolov \(2013\)](#), [Rad, Low, and Faff \(2016\)](#), [Green, Hand, and Zhang \(2017\)](#), [Clegg and Krauss \(2018\)](#), among others.

#### 4.1.5. Industry breakdown

Coming from the LSTM's ability to identify structure, we next analyze potential preferences for certain industries in the  $k = 10$  portfolio. Specifically, we consider the difference between the share of an industry in the  $k = 10$  portfolio and the share of that industry in the S&P 500 at that time. A positive value indicates that the industry is overweighted by the LSTM network, and a negative value indicates that it is underweighted.

[Fig. 6](#) depicts our findings for the most interesting industries – oil and gas, technology, financials, and all others. First, we see that there is a significant overweight of technology stocks building up end of the 90s – corresponding to the growing dot-com bubble and its bust. Second, we observe a rise in financial stocks around the years 2008/2009 – corresponding to the global financial crisis. And third, oil and gas stocks gain in weight as of 2014 – falling together with the recent oil glut and the significant drop in crude oil prices. Note: a more detailed breakdown depicting the relative overweight for each of the GICS industries individually for the top  $k$  and the flop  $k$  portfolio is provided in the Appendix.<sup>8</sup> It is interesting to see that the overweight in each industry adequately captures major market developments. We hypothesize that this behavior is driven by increasing volatility levels, and further elaborate on that point in the following section.

#### 4.2. Common patterns in the top and flop stocks

Machine learning approaches – most notably artificial neural networks – are commonly considered as black-box methods. In this section, we aim for shining light into that black-box, thus unveiling common patterns in the top and flop stocks.

First, we conduct a very simple yet effective analysis. For every day, we extract all 240-day return sequences for the top and flop  $k$  stocks.<sup>9</sup> Then, we stack all  $5750 \times 10$  top and the same number of flop sequences on top of each other. For better representation, we accumulate the 240 returns of each sequence to a return index, starting at a level of 0 on day  $t - 240$  and then average these return index sequences. We hence obtain two generalized sequences,

containing the patterns of the top 10 and of the flop 10 stocks. Results are depicted in [Fig. 7](#), contrasted to the behavior of the cross-section across all stocks (mean). We see that the top and the flop stocks both exhibit below-mean momentum in the sense of [Jegadeesh and Titman \(1993\)](#), i.e., they perform poorly from day  $t - 240$  until day  $t - 10$ , compared to the cross-section. From day  $t - 9$  until  $t$  (note: the prediction is made on day  $t$ ), the top stocks start crashing at accelerating pace, losing about 50 percent of what they have gained during the previous 230 days on average. By contrast, the flop stocks show an inverse pattern during the past 10 days prior to trading, and exhibit increasingly higher returns. It is compelling to see that the LSTM extracted such a strong commonality among the flop stocks and the top stocks.

Second, based on this visual insight, we construct further time-series characteristics for the top and flop stocks. Thereby, we follow the same methodology as above for generating the descriptive statistics, i.e., we compute the 240-day return sequence for each stock, calculate the desired statistic, and average over all  $k$  stocks, with  $k \in \{1, 5, 10, 100, 200\}$ . Specifically, we consider the following statistics:

- (Multi-)period returns, as defined in [Section 3.2](#), with  $m \in \{1, 5, 20, 240\}$ , denoted as  $\text{Return\_t-t-m}$  in the graphic, where  $m$  is counting backwards from day  $t$ , the last element of the sequence (i.e., the day on which the prediction for  $t + 1$  is made). Moreover, we consider the cumulative return from day  $t - 20$  of the sequence until day  $t - 240$  of the sequence, denoted as  $\text{Return\_t-20\_t-240}$ .
- Sample standard deviations, computed over the same time frames as above, and following the same naming conventions.
- Sample skewness and kurtosis over the full 240 days of each sequence.
- The coefficients of a Carhart regression in the sense of [Gatav, Goetzmann, and Rouwenhorst \(2006\)](#), [Carhart \(1997\)](#). Thus, we extract the alpha of each stock ( $\text{FF\_Alpha}$  – denoting the idiosyncratic return of the stock beyond market movements), the beta ( $\text{FF\_Mkt-RF}$  – denoting how much the stock moves when the market moves by 1 percent), the small minus big factor ( $\text{FF\_SMB}$  – denoting the loading on small versus large cap stocks), the high minus low factor ( $\text{FF\_HML}$  – denoting the loading on value versus growth stocks), the momentum factor ( $\text{FF\_Mom}$  – denoting the loading on the momentum factor in the sense of [Jegadeesh and Titman \(1993\)](#), [Carhart \(1997\)](#), the short-term reversal factor ( $\text{FF\_ST\_Rev}$  – denoting the loading on short-term reversal effects) and the R squared ( $\text{FF\_R\_squared}$  – denoting the percentage of return variance explained by the factor model). Please note that these coefficients refer to the individual stocks' 240 days history prior to being selected by the LSTM for trading and not to the exposure of the resulting LSTM strategy to these factors (see [Section 4.3](#) for this analysis).

<sup>8</sup> We thank an anonymous referee for this suggestion.

<sup>9</sup> A return sequence is generated as described in [Section 3.2](#).

Fig. 7. Averaged, normalized return index of top and flop 10 stocks over sequence of the 240 one day returns prior to trading for LSTM strategy.

Fig. 8. Time-series characteristics of top and flop  $k$  stocks for LSTM strategy. Statistics are first computed over the 240-day return sequences for each stock in the top or flop  $k$ , as described in the bullet list in Section 4.2 (including naming conventions) and then averaged over all top  $k$  or all flop  $k$  stocks. The mean is calculated similarly, however across all stocks. Note that there is a color-coding along each row, separately for top and flop  $k$  stocks. Thereby, the darker the green, the higher the value, and the darker the red, the lower the value. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

Results are shown in Fig. 8. The graphical patterns from the last paragraph now become apparent in a quantitative manner – across different values of  $k$ . First, the top stocks exhibit highly negative returns in the last days prior to the prediction, and the flop stocks highly positive returns. This behavior corresponds to short-term reversal strategies, as outlined in Jegadeesh (1990), Lehmann (1990), Lo and MacKinlay (1990) – to name a few. The LSTM network seems to independently find the stock market anomaly, that stocks that sharply fall in the last days then tend to rise in the next period and vice versa. The effect is stronger, the smaller  $k$ , i.e., the lower the number of stocks considered in the portfolio. Second, both top and flop stocks exhibit weak momentum in the sense of Jegadeesh and Titman (1993). For example, the top 10 stocks show an average momentum of 9.1 percent from day  $t - 240$  until day  $t - 20$  of the sequence, compared to 11.7 percent, i.e., the mean across all stocks. The flop stocks exhibit a similar pattern. The smaller  $k$ , the stronger the underperformance with respect to the momentum effect. Third, when considering standard deviation, it becomes obvious that volatility plays an important role (see also LeBaron, 1992). Clearly, high volatility stocks are preferred compared to the market, and volatility is increasing for the more extreme parts of the ranking. Volatility in the sense of beta can be an important return predictive signal – see Baker, Bradley, and Wurgler (2011), Frazzini and Pedersen (2014),

Hong and Sraer (2016), and a higher beta is a key characteristic of the selected stocks. Also, skewness is similar to the general market, and the returns of the top and flop stocks are more leptokurtic than the general market – a potential return predictive signal remotely relating to the works of Kumar (2009), Boyer, Mitton, and Vorkink (2010), Bali, Cakici, and Whitelaw (2011) on stocks with “lottery-type” features. Finally, we see that the above mentioned time-series characteristics are also confirmed in the regression coefficients. Top and flop  $k$  stocks exhibit higher beta, a negative loading on the momentum factor and a positive loading on the short-term reversal factor – with the respective magnitude increasing with lower values for  $k$ . We observe a slight loading on the SMB factor, meaning that smaller stocks among the S&P 500 constituents are selected – which usually have higher volatility.

Given that the LSTM network independently extracted these patterns from 240-day sequences of standardized returns, it is astonishing to see how well some of them relate to commonly known capital market anomalies. This finding is compelling, given that none of the identified characteristics is explicitly coded as feature, but instead derived by the LSTM network all by itself – another key difference to the memory-free models, such as the random forest, who are provided with multi-period returns as features.

### 4.3. Sources of profitability

**Simplified trading strategy:** In this section, we build on the previous analysis and construct a simplified trading strategy. From Figs. 7 and 8, we see that the most dominant characteristic is the slump or steep rise in returns in the last days prior to trading. On a similar note, Krauss et al. (2017) find that the last returns are the most important variables for their machine learning models, and so do Moritz and Zimmermann (2014). For the sake of simplicity, we build on this most salient point, and loosely follow Jegadeesh (1990), Lehmann (1990), two of the creators of the short-term reversal anomaly. Specifically, we go long the top  $k$  stocks with the most negative 5-day cumulative return prior to the trading day, and short the flop  $k$  stocks with the most positive 5-day cumulative return prior to the trading day – all equal-weight. For this very simple yet transparent strategy, we find average daily returns of 0.23 percent, prior to transaction costs, or 0.03 percent after transaction costs. We hence see that capitalizing only on the most prominent feature, i.e., the past 5-day cumulative return, merely yields about 50 percent of the returns of the LSTM strategy prior to transaction costs. After transaction costs, the short-term reversal strategy loses its edge, contrary to the LSTM. Hence, we may cautiously conclude that additional explanatory power is contained in the other features, forming more subtle patterns not directly discernible from the aggregated perspective in Fig. 8. Building on this finding, we next move on and evaluate the exposure of LSTM returns to common sources of systematic risk.

**Exposure to systematic sources of risk:** As commonly performed in portfolio analysis and similar to Krauss et al. (2017), we evaluate the exposure of the long-short portfolio to common sources of systematic risk. We use the Fama–French three factor model (FF3) as in Fama and French (1996), enhanced by three additional factors. It thus consists of a market factor, a factor measuring exposure to small minus big capitalization stocks (SMB), and a factor measuring exposure to high minus low book-to-market stocks (HML). In addition, we include a momentum factor (Carhart, 1997), a short-term reversal factor (Gatev et al., 2006), and a long-term reversal factor. All data used for these factor models are obtained from Kenneth French's website.<sup>10</sup> The underlying idea is to measure additional exposure to cross-sectional price dynamics. Our findings are summarized in Table 4. At first, we observe that the LSTM returns exhibit by far the lowest coefficient of determination of 0.0330 among all models. In other words – only a fraction of daily LSTM raw returns of 0.46 percent can be explained by such common sources of systematic risk. Indeed, an alpha of 0.42 percent per day remains (intercept). By contrast, the RAF has a higher coefficient of determination of 0.1338, and only 0.34 percent of daily alpha remain (compared to raw returns of 0.43 percent). Even though  $R^2$  is low (which can often be the case in financial research – see Gatev et al., 2006) – we can still compare factor loadings with our expectations. The LSTM is basically market-neutral, meaning that the long and the short portfolio (in which we invest equal dollar amounts) exhibit similar beta. By contrast, the other strategies seem to favor slightly higher beta stocks on the long leg than on the short leg. The SMB factor is generally non-significant and close to zero across all models. Exposure to HML varies across strategies. Whereas the LSTM favors glamour stocks (negative and significant loading), the RAF has a tendency to select value stocks (positive and significant loading); DNN and the simple logistic regression do not have any exposure. Most interesting are the factors capturing cross-sectional price dynamics, given that they are largely in line with the features we are feeding. We see that all models have positive and statistically significant exposure towards the momentum

**Table 4**

Exposure to systematic sources of risk of the LSTM, RAF, DNN, and LOG strategies prior to transaction costs from December 1992 to October 2015. Standard errors are depicted in parentheses.

\*\*\*  $p < .001$ , \*\*  $p < .01$ , \*  $p < .05$ .

and the short-term reversal factor – meaning that shorter-term cross-sectional price dynamics are captured. Interestingly enough, these price-based factor loadings are more dominant for the logistic regression compared to the LSTM. This increase in loadings may be due to the fact that the simpler model is structurally unable to extract higher-order patterns from the supplied features – given that we did not feed any interactions. Lastly, the long-term reversal factor is insignificant for the LSTM, and has slightly negative loadings for the other strategies, albeit at lower levels of significance. We believe that this factor has generally lower explanatory power, given that we are addressing a very short trading horizon. In a nutshell, the LSTM returns can barely be explained by systematic sources of risk – and much less so than those of the other machine learning models we have deployed.

### 4.4. Robustness to market microstructure

A key result of the last subsection is that the LSTM-based stock selection exhibits similarities to a typical contrarian investment strategy. Microstructural effects, particularly the bid-ask bounce, are commonly known to introduce an upward bias to such contrarian investment strategies – see Conrad and Kaul (1989), Jegadeesh (1990), Jegadeesh and Titman (1995), Gatev et al. (2006). The underlying reason is simple. The LSTM strategy tends to buy recent losers and sell recent winners. Conditional on being among the top  $k$  stocks, the winner's quote is more likely to be an ask quote, and conditional on being among the flop  $k$  stocks, the loser's quote is more likely to be a bid quote – similar to the reasoning on the contrarian investment strategy presented in Gatev et al. (2006). Implicitly, we would thus be buying at the bid in case of the losers, and selling at the ask in case of the winners. The inverse applies when covering positions – part of the surge in prices of the recent loser may be driven by the jump from bid to ask, and part of the slump in prices of the recent winner may be driven by the jump from ask to bid. In light of these considerations, it is necessary to analyze the robustness of our findings.<sup>11</sup> There are several solutions to this issue.

First, longer trading horizons are typically more robust to microstructural effects. Following e.g., Lehmann (1990) in his short-

<sup>10</sup> We thank French for providing all relevant data for these models on his website.

<sup>11</sup> We thank an anonymous referee for suggesting this robustness check.

**Table 5**

Panel A names the LSTM model variants, with different trading frequencies and types of execution ( $M_1$  through  $M_5$ ). Panels B, C, and D illustrate performance characteristics of the  $k = 10$  portfolio, before and after transaction costs for all five model variants, compared to the general market (MKT) from January 1998 to October 2015. MKT represents the general market as in Kenneth R. French's data library, see [here](#). Panel B depicts daily return characteristics. Panel C depicts daily risk characteristics. Panel D depicts annualized risk-return metrics. Newey–West standard errors are used.

term reversal strategy or [Huck \(2009, 2010\)](#) in his machine learning strategies, we introduce a weekly variant of the LSTM strategy – effectively bridging the gap between lower turnover (weekly vs. daily), and retaining a sufficient number of training examples for the LSTM to successfully extract structure from the data. The latter excludes a monthly variant, without significantly changing the study design. Specifically, we design the LSTM in full analogy to the cornerstones outlined in [Section 3](#), but on a 5-day instead of a 1-day horizon.<sup>12</sup> Moreover, we implement five overlapping portfolios of LSTM strategies with a 5-day forecast horizon to avoid a bias introduced by the starting date ([Jegadeesh & Titman, 1993](#)). Thereby, each portfolio is offset to the other by one trading day, and returns are averaged across all portfolios. Note that we log the invested capital market-to-market on a daily basis for all five portfolios, so we are able to exhibit daily returns for the sake of comparability.

Second, execution on volume-weighted-average-prices (VWAPs) is more realistic and much less susceptible to bid-ask bounce (see for example, [Lee, Chan, Faff, & Kaleb, 2003](#)). Hence, we use minute-binned transaction data from January 1998 to October 2015 for all S&P 500 stocks from QuantQuote to create VWAPs, which we use for feature engineering, for target creation, and for backtesting – see [Section 3](#).<sup>13</sup> Specifically, we divide the 391 minute-bins of each trading day (starting at 09:30 and ending at 16:00, includ-

ing the opening) in 23 bins of 17 minutes duration, so we obtain 23 VWAPs. We use the 22nd VWAP as anchor point for creating features, and the 23rd VWAP for executing our trades, and create features in full analogy to [Section 3.2](#).

Third, a one-day-waiting rule as in [Gatev et al. \(2006\)](#) is a proper remedy against bid-ask bounce. Specifically, we delay the execution by one entire trading day after signal generation. This rule only makes sense for the weekly strategy. In case of the daily strategy, the delay covers the entire forecast horizon, rendering the predictions null and void.

Fourth, for the sake of completeness, we use transaction costs of 5 bps per half-turn throughout this paper – a fairly robust value for U.S. large caps. For example, [Jha \(2016\)](#) assumes merely 2 bps for the largest 500 stocks of the U.S. stock universe over a similar time horizon.

In a nutshell, we run the following robustness checks on the LSTM strategy. Model  $M_1$  is the baseline, showing the results of the standard LSTM strategy as discussed in the previous sections, i.e., with daily turnover and execution on the close, but constrained to the time frame of the QuantQuote data set from 1998 to 2015. Model  $M_2$  shows the effects when executing this strategy on the VWAP instead of the closing price. Models  $M_3$ – $M_5$  are weekly variants of the baseline strategy. Thereby,  $M_3$  is executed on the closing price,  $M_4$  on the VWAP, and  $M_5$  with a one-day-waiting rule on the closing price. The results of these variants are depicted in [Table 5](#) – before and after transaction costs of 5 bps per half-turn.

After transaction costs, the baseline LSTM strategy  $M_1$  results in average returns of 0.20 percent per day on the shorter time frame from 1998 to 2015. Executing on VWAPs instead of at the closing price in case of model  $M_2$  leads to a deterioration to 0.16 percent per day – still statistically significant with a *t*-statistic above 5 and economically meaningful with returns of 43 percent p.a. The weekly strategies generate similar returns per day,

<sup>12</sup> As such, the time step, the forecast horizon, and the raw returns comprise a duration of 5 days. In analogy, the sequence length is 52 to reflect one year, consisting of 52 weeks.

<sup>13</sup> To be able to evaluate the performance of the LSTM over the whole period from January 1998 until October 2015, we use the Thomson Reuters dataset to train the model on the first 750 days prior to January 1998. Out-of-sample prediction (trading) is then performed on the VWAPs calculated from the QuantQuote data. In all following study periods, we train and predict on the QuantQuote data.

**Fig. 9.** Contrast LSTM model variants' performance from January 1998 to October 2015 for the  $k = 10$  portfolio, i.e., development of cumulative profits on 1 USD average investment per day after transaction costs.

i.e., 0.11 percent in case of  $M_3$  (execution on close), 0.09 percent in case of  $M_4$  (execution on VWAP), and 0.09 percent in case of  $M_5$  (execution on close, one-day-waiting) – all of them statistically and economically significant with  $t$ -statistics above 3 and annualized returns above 20 percent. The rest of the table reads in full analogy to Table 3, and shows a relative outperformance of the LSTM strategy compared to the general market, after robustness checks.

In recent years, however, as depicted in Fig. 9, we see that returns flatten out, so the LSTM edge seems to have been arbitrated away. Despite of this fact, model performance is robust in light of market frictions over an extended period of time, i.e., from 1998 up until 2009, with particular upward spikes in returns around the financial crisis.

## 5. Conclusion

In this paper, we apply long-short term memory networks to a large-scale financial market prediction task on the S&P 500, from December 1992 until October 2015. With our work, we make three key contributions to the literature: the first contribution focuses on the large-scale empirical application of LSTM networks to financial time series prediction tasks. We provide an in-depth guide, closely following the entire data science value chain. Specifically, we frame a proper prediction task, derive sensible features in the form of 240-day return sequences, standardize the features during preprocessing to facilitate model training, discuss a suitable LSTM architecture and training algorithm, and derive a trading strategy based on the predictions, in line with the existing literature. We compare the results of the LSTM against a random forest, a standard deep net, as well as a simple logistic regression. We find the LSTM, a methodology inherently suitable for this domain, to beat the standard deep net and the logistic regression by a very clear margin. Most of the times – with the exception of the global financial crisis – the random forest is also outperformed. Our findings of statistically and economically significant returns of 0.46 percent per day prior to transaction costs posit a clear challenge to the semi-strong form of market efficiency, and show that deep learning could have been an effective predictive modeling technique in this domain up until 2010. These findings are largely robust in light of market frictions, given that profitability remains statistically and economically significant when executing the daily LSTM strategy on VWAPs instead of closing prices, and when running a weekly variant of the LSTM strategy with a one-day waiting period after signal genera-

tion. As of 2010, the markets exhibit an increase in efficiency with respect to the machine learning methods we deploy, with LSTM profitability fluctuating around zero and RAF profitability dipping strictly into the negative domain.

Also, the conceptual and empirical aspects on LSTM networks outlined in this paper go beyond a pure financial market application, but are intended as guideline for other researchers, wishing to deploy this effective methodology to other time series prediction tasks with large amounts of training data.

Second, we disentangle the black-box “LSTM”, and unveil common patterns of stocks that are selected for profitable trading. We find that the LSTM portfolio consist of stocks with below-mean momentum, strong short-term reversal characteristics, high volatility and beta. All these findings relate to some extent to existing capital market anomalies. It is impressive to see that some of them are independently extracted by the LSTM from a 240-day sequence of standardized raw returns. It is subject to future research to identify further, more subtle patterns LSTM neural networks learn from financial market data, and to validate the profit potential of these patterns in more refined, rules-based trading strategies.

Third, based on the common patterns of the LSTM portfolio, we devise a simplified rules-based trading strategy. Specifically, we short short-term winners and buy short-term losers, and hold the position for one day – just like in the LSTM application. With this transparent, simplified strategy, we achieve returns of 0.23 percent per day prior to transaction costs – about 50 percent of the LSTM returns. Further regression analysis on common sources of systematic risk unveil a remaining alpha of 0.42 percent of the LSTM prior to transaction costs and generally a lower risk exposure compared to the other models we deploy.

Overall, we have successfully demonstrated that an LSTM network is able to effectively extract meaningful information from noisy financial time series data. Compared to random forests, standard deep nets, and logistic regression, it is the method of choice with respect to predictional accuracy and with respect to daily returns after transaction costs. As it turns out, deep learning – in the form of LSTM networks – hence seems to constitute an advancement in this domain as well.

## Appendix. Detailed industry breakdown

Fig. A1.

**Fig. A1.** Time-varying share of industries in the “top-10” and “flop-10” portfolio minus share of these industries in the S&P 500, calculated over number of stocks. A positive value indicates that the industry is overweighted and vice versa.
